AN EVALUATION OF COATED MOLYBDENUM AND COLUMBIUM ALLOYS IN HIGH-TEMPERATURE SUPERSONIC AIRSTREAMS

By Irvin M. Miller Langley Research Center

SUMMARY

An experimental study was made to investigate the oxidation behavior of four commercially coated refractory metal systems in supersonic airstreams: Durak B and Vought IX coated TZM and Cr-Ti-Si and Cr-MoSi₂ coated Cb-752. Cyclic coating life and temperature data were obtained on 0.375-inch-diameter (0.953 cm) blunt-nose models at surface temperatures from 2600° to 3000° F (1700° to 1920° K) and at air stagnation pressures behind the shock wave of 0.03, 0.10, and 5.5 atmospheres. The oxidation behavior of uncoated molybdenum- and columbium-alloy models of the same size and shape was also studied in the same test environments.

Coating life of the TZM/Durak B, Cb-752/Cr-Ti-Si, and Cb-752/Cr-MoSi₂ systems was significantly lower at air stagnation pressures of 0.10 and 0.03 atmosphere than at 5.5 atmospheres. At these low-pressure conditions, the coating life of these three coating systems did not exceed 32 minutes. The uncoated columbium alloys oxidized catastrophically at air stagnation pressures of 0.10 and 0.03 atmosphere in less than 20 seconds at temperatures well below the melting points of the alloys.

INTRODUCTION

Alloys of the refractory metals, such as molybdenum and columbium, are among the materials being considered for radiatively cooled heat shields in lifting reentry vehicles. These heat shields are expected to have maximum surface temperatures from 2040° to 3540° F (1390° to 2220° K) at less than normal atmospheric pressure. (See ref. 1.) Heat shields using the refractory metals are capable of multiple reentries, depending on the time-temperature environment. However, these alloys begin to oxidize below 2000° F (1370° K) and form oxides which do not protect the base metal. Molybdenum alloys oxidize to a gaseous product with a consequent loss of material. Columbium alloys oxidize to porous oxide scales which permit further alloy oxidation. Numerous attempts have been made to increase the oxidation resistance of these alloys to an acceptable level without degrading alloy properties, but none have been successful. (See refs. 2, 3, and 4.) Therefore, refractory inorganic coatings were developed to protect these alloys from oxidation.

To evaluate the oxidation resistance of coated refractory alloys, many oxidation studies have been made in static or low flow-rate environments. (See ref. 5.) These studies were usually carried out at an air pressure of 1 atmosphere (0.1013 MN/m^2) and for 1-hour exposure cycles. Some studies were made in static environments at reduced pressures. (See ref. 6.) Very few studies have been made to determine the oxidation response of these coated alloy systems in dynamic environments.

A dynamic environment has two possible effects on a coated surface which are not present in a static environment: one is a shearing effect of a liquid or loose solid at the surface; the other is a more rapid transport of oxygen to the surface and a more rapid diffusion from the surface of any gas produced at the surface. Very limited dynamic test data exist for a pressure range from 0.01 to 1 atmosphere; therefore, it was difficult to evaluate the effects of a dynamic environment on coating performance. (For example, see refs. 7, 8, and 9.)

The primary purpose of the present experimental study was to investigate the oxidation behavior of selected coating-alloy systems in a range of dynamic environments. Another purpose was to compare coating performance in dynamic environments with static test data in the literature. Since a coating failure could expose the substrate material to oxidation, a final purpose was to determine the oxidation behavior of uncoated alloys in the same dynamic environments used for the coated alloys.

The experimental program was carried out with four commercially coated refractory metal systems: Durak B and Vought IX on molybdenum alloy TZM and Cr-Ti-Si and Cr-MoSi₂ on columbium alloy Cb-752. These two alloys and columbium alloy B-66 were used in uncoated-alloy oxidation studies.

Two test parameters considered important in the response of coated refractory metals to earth reentry flight environments are surface pressure and surface temperature. In the tests reported herein, the stream conditions produced stagnation pressures behind the shock wave $p_{t,2}$ of 0.03, 0.10, and 5.5 atmospheres and surface temperatures from 2545° to 3180° F (1670° to 2020° K) on the coated models. The same stream conditions were used for the uncoated alloy models and produced the same stagnation pressures, but surface temperatures ranged from 2770° to 4400° F (1795° to 2700° K).

METHODS AND TESTS

Models and Techniques

The refractory metal models used in the present study were machined from solid stock to a 0.375-inch-diameter (0.953 cm) blunt-nose shape as shown in figure 1. This shape was selected in an attempt to obtain a more uniform heating rate and surface temperature on the face of the model than could be obtained on a hemispherical model (see

THE REPORT OF THE PARTY OF THE

ref. 10). Maximum heating rate limitations in two of the test facilities made the small model size necessary to obtain surface temperatures in the range of interest. Early tests produced surface temperatures lower than expected, and this was corrected by installing behind the model an alumina insulator which minimized heat conduction losses from the back of the model to the water-cooled holder as shown in figure 2.

The two alloys and four coatings used in the tests are listed in table 1, along with the one additional alloy which was tested in the uncoated condition. Alloy compositions and coating compositions, processes, and thicknesses are given in the table. The coatings are all commercially available silicide-base coatings. They were selected on the basis of superior oxidation protection in static oxidation tests made by the University of Dayton Research Institute. (See ref. 11.) Nominal coating thicknesses listed in table 1 are contract specifications consistent with values reported in the literature (see ref. 12).

Both uncoated and coated models were tested at three stagnation pressure levels – 5.5, 0.10, and 0.03 atm – with each pressure level being obtained in a different facility, as shown in table 2. The observed surface-temperature ranges are listed for both the coated and uncoated models. The use of different facilities prevented the exact duplication of surface temperatures at all three pressure conditions. Surface temperatures on the coated models were approximately the same in two of the facilities (for pressures of 5.5 and 0.10 atm) but were approximately 200° to 400° F (111° to 167° K) higher in the third facility (for a pressure of 0.03 atm) due to a minimum heating rate limitation at this pressure condition. All uncoated models were tested in the same supersonic airstreams used for the coated models, but surface temperatures were higher on the uncoated models due to the exothermic heat of reaction between the metal alloy and the heated airstream.

The three facilities used in this study are listed in table 2. The Langley 11-inch ceramic-heated tunnel is described in reference 13. It was fitted with a Mach 2 nozzle having an exit diameter of 1.332 in. (3.38 cm) and exhausting to the atmosphere. Figure 3 shows a coated model in test position in this facility. Each coated model was tested in 8-min cycles. The Langley 20-inch hypersonic arc-heated tunnel is described in references 14 and 15. It was fitted with a Mach 6 nozzle having an exit diameter of 6.6 in. (16.76 cm). Figure 4 shows four coated models in test position in this facility. These models were tested in 5-min cycles. The high-enthalpy arc tunnel at the Langley Research Center is described in the appendix. Figures 5 and 6 show models in test position in this facility. These models were also tested in 5-min cycles.

The models were held in the test streams by water-cooled stings. A model holder used in the ceramic-heated tunnel is shown in figure 2. A model holder used to test 4 models simultaneously in the two arc-heated facilities is shown in figure 7. The models

in this holder are located on a diameter concentric with the diameter of the test stream. The area blocked by the model holder is about 23 percent of the cross-sectional area of the test stream. Results of unpublished surveys of pressure and heating rate in the highenthalpy arc tunnel have indicated that the four models were in a region of uniform flow and were exposed to the same test conditions. A similar result has been obtained for the 20-inch hypersonic arc-heated tunnel with regard to pressure. No detailed surveys of the heating rate in this tunnel have been made, but temperature surveys made with models of like composition indicated that the four models were probably exposed to the same test conditions in the tunnel.

In all three test facilities the test procedure was generally the same. After flow stabilization of the airstream was obtained, motion-picture cameras and a photographic pyrometer were turned on and the model, or models, was inserted into the test stream. Surface temperature on the coated model stabilized in about 20 seconds after insertion. An optical pyrometer was used to observe the model under test. The model was removed from the test stream at the specified test time, or earlier if it appeared to oxidize rapidly. In tests of coated models, coating failure (i.e., exposure of the substrate) was detected either during the test cycle by observation of a melting or flame phenomenon or after the test cycle by eye or with the aid of a low-power microscope. The life of a coating is defined as the cumulative test time to failure.

Instrumentation and Data Reduction

The surface temperature of the model was measured by a photographic pyrometer, which is described in reference 16. Since the model could only be photographed from the side, the area selected for temperature measurement and resolved by the readout system was located on the curved shoulder of the model adjacent to the stagnation zone, as shown in figure 8. Temperature traverses across the curved shoulder of several models indicated a linear temperature decrease with axial distance from the front face. A linear extrapolation to the visible edge of the front face or stagnation zone indicated that the temperature measured on the shoulder was about 2 percent lower than the extrapolated value at the edge of the stagnation zone. The surface temperature at the edge of the stagnation zone is believed to be representative of the temperature in the stagnation zone, based on the assumption of a constant heating rate in this zone (see ref. 10). Therefore, measured surface temperatures are believed to be about 2 percent below the stagnation-zone surface temperatures. Surface brightness temperatures were corrected for spectral emittance according to the assumed values listed in table 3 and cited in references 17 and 18. The photographic pyrometer has a measurement imprecision of ±2 percent. A ±20-percent error in the assumed emittance values would result in a measurement error of about ± 2 percent in the temperature range from 2500° to 3000° F (1645° to 1920° K). (See ref. 16.) Temperature data were recorded every 1 or 2 sec for

all test runs. The temperature reported for each coated model under test is the average of the temperatures measured in two or more test cycles. A 2-percent temperature variation was observed between test cycles.

RESULTS AND DISCUSSION

Uncoated-Model Tests

If a coating failure occurs on a coated alloy and exposes that alloy to the oxidizing atmosphere, the exposed alloy could oxidize as an uncoated alloy. Therefore, it was important to characterize the oxidation behavior of uncoated alloys in the same dynamic environments used for the coated alloys. The responses of the three uncoated metals, which were exposed to the same dynamic oxidizing environments as the coated metals, are listed in table 4 and are shown in figure 9. In figure 9, "noncatastrophic" oxidation describes a test in which no liquid phase formed; "catastrophic" oxidation describes a test in which a liquid phase formed with a consequent rapid removal of material.

Molybdenum alloy TZM.- At 5.5 atm, the surface temperatures of the two uncoated models of molybdenum alloy TZM were well above the surface temperatures of 2655° to 2680° F (1730° to 1745° K) for the coated molybdenum-alloy models in the same stream (see tables 2 and 4). A liquid phase was observed to form in less than 30 seconds at temperatures well below the melting point of the alloy (see table 4 and fig. 9). A similar response was reported for pure molybdenum models exposed to a 10.5-atm airstream in reference 19. At 0.1 atm, temperatures of 3220° to 3315° F (2045° to 2095° K) were observed, but no liquid phase formed. At 0.03 atm, temperatures of 3600° to 3845° F (2255° to 2390° K) were observed. A liquid phase formed on one of the four models at a temperature of 3835° F (2385° K), which is well below the melting point of the alloy. This liquescent phenomenon was similar to that observed for this alloy at 5.5 atm except that the model did not recede rapidly at 0.03 atm. The surface temperatures at 0.03 atm were higher than those at 0.10 atm, which was probably due to the higher heating rate at 0.03 atm (see table 2).

Columbium alloys Cb-752 and B-66. The uncoated columbium alloys (Cb-752 and B-66) are discussed together because of similarities in oxidation response at all three pressure conditions. (See table 4 and fig. 9.) A liquid phase was observed to form on both alloys at all three pressure levels and at surface temperatures well below the melting point of the metal. This liquescent phenomenon occurred in less than 25 sec at 5.5 atm and in less than 20 sec at 0.03 and 0.10 atm. This phenomenon has been observed on columbium metal in a static oxidation test at 1 atm in oxygen and at 2550° F (1670° K) (see ref. 20). The observed temperatures at which liquid formed are near the melting points of the base-metal oxides (see ref. 21); this result suggests that one or more of these oxides may have formed on these alloys.

From the foregoing discussion on the oxidation response of the uncoated metals, it is concluded that at the low pressures of interest for reentry flight missions, the exposure of any of the columbium alloys of this study by a coating failure could result in the catastrophic oxidation of the base metal in 20 sec or less.

Coated-Model Tests

All four coating-alloy systems are represented in figures 10 and 11 which show magnified front-face views of some of the models tested in the three dynamic environments. In general, the response shown by each of the models in these figures illustrates failure mode. Average surface temperature and coating life are listed for each model shown. The coating life of the coated Cb-752 models tested at 5.5 atm is shown as >72 min, meaning that testing was discontinued after 72 min of total test time without visual evidence of coating failure. Table 5 lists the test results for the coated TZM and Cb-752 models and figures 12 and 13 show these data plotted for each coating system.

Molybdenum alloy TZM.- Figure 12 shows that the coating life of the TZM/Durak B system was significantly lower at 0.10 and 0.03 atm than at 5.5 atm. At the lower pressures, coating life did not exceed 32 min. The lower lifetimes at reduced pressure may be due to a low-pressure decomposition of the protective silica layer that forms on the surface of silicide-base coatings. (See ref. 9.)

A comparison was made between the coating life of the TZM/Durak B system in the dynamic oxidation environment of this study and the coating life of this system in a static oxidation environment (see table 6(a)). At approximately the same pressure of 0.03 atm and average coating life, surface temperatures for the dynamic tests were about 200° to 300° F (111° to 167° K) lower than they were for the continuous static tests. This behavior is equivalent to lower coating life at a given temperature and is not surprising in view of the dynamic environment and short test cycle time (see ref. 7).

Lifetimes for the TZM/Vought IX system varied considerably at both high and low pressures, probably an indication of coating nonuniformity among models (see fig. 12). Because of this large variation, no trend with pressure could be defined.

Columbium alloy Cb-752.- Since the behavior of the Cr-Ti-Si and Cr-MoSi₂ coatings on columbium alloy Cb-752 was similar at all three test conditions, the response of these coatings will be discussed jointly.

At 5.5 atm, tests were stopped on both coatings when no failure occurred after a total test time of 72 min (see fig. 13). At 0.10 atm, both coatings failed in less than 20 min. At 0.03 atm, both coatings failed in 32 min or less. These results indicate that a sharp drop in coating life occurred for the Cb-752/Cr-Ti-Si and Cb-752/Cr-MoSi₂ systems when air stagnation pressure was reduced from 5.5 to 0.10 atm. At the lower pressures of 0.10 and 0.03 atm, coating life did not exceed 32 min.

The response of the Cb-752/Cr-Ti-Si system in the dynamic environment of this study is compared with the response of this system in a static environment at approximately the same pressure conditions (see table 6(b)). The results indicate that the static or dynamic state of the environment was apparently not critical to coating performance at an air pressure of 0.03 atm and at surface temperatures of 2880° to 3180° F (1855° to 2020° K) as evidenced by the low coating life and the melting of the models.

CONCLUDING REMARKS

An experimental study was made to investigate the oxidation behavior of uncoated and commercially coated molybdenum alloy TZM and columbium alloy Cb-752 in supersonic airstreams.

Coating life for the TZM/Durak B system was lower at air stagnation pressures of 0.10 and 0.03 atmosphere than at 5.5 atmospheres. At the lower pressures, coating life did not exceed 32 minutes. At approximately the same pressure of 0.03 atmosphere and average coating life, surface temperatures for the dynamic tests were 200° to 300° F (111° to 167° K) lower than that reported for continuous static tests.

No coating-life trend with pressure was found with the TZM/Vought IX system due to the large variation of coating life at air stagnation pressures of 5.5, 0.10, and 0.03 atmospheres.

A sharp drop in coating life occurred for the Cb-752/Cr-Ti-Si and Cb-752/Cr-MoSi₂ systems when air stagnation pressure was reduced from 5.5 atmospheres to 0.10 atmosphere. At air stagnation pressures of 0.10 and 0.03 atmosphere, coating life did not exceed 32 minutes. The static or dynamic state of the environment was not found to be critical to the coating performance of the Cb-752/Cr-Ti-Si system at an air pressure of 0.03 atmosphere and at surface temperatures of 2880° to 3180° F (1855° to 2020° K).

The uncoated columbium alloys (Cb-752 and B-66) tested in the same reduced-pressure dynamic test streams used for the coated alloys (0.03 and 0.10 atmosphere) were found to oxidize catastrophically by forming liquid phases in less than 20 seconds. Liquescent temperatures were below the melting points of the uncoated alloys.

The uncoated molybdenum alloy (TZM) and columbium alloys (Cb-752 and B-66) tested in the same high-pressure dynamic test streams used for the coated alloys (5.5 atmospheres) were found to oxidize catastrophically in less than 30 seconds. Liquescent temperatures were below the melting points of the uncoated alloys.

APPENDIX

THE HIGH-ENTHALPY ARC TUNNEL AT THE LANGLEY RESEARCH CENTER

The high-enthalpy arc tunnel at the Langley Research Center is a materials test facility capable of producing high-temperature supersonic gas streams having total enthalpies in the range from 10 000 to 12 000 Btu/lbm (23 to 28 MJ/kg). The high-temperature supersonic gas stream, consisting of air or nitrogen, is produced by passing the gas through an arc heater and then expanding it through a conical nozzle to an evacuated test section.

To provide a wide range of test conditions, three nozzle sizes and a range of arc-chamber pressure are available. All three nozzles have throat diameters of 0.75 in. (1.9 cm), and are provided with exit diameters of 2 in. (5.1 cm), 4.6 in. (12 cm), and 7.6 in. (19 cm). Arc-chamber pressure may be varied between 1.0 and 3.3 atm. The general arrangement of this facility is shown in figure 6.

NATIONAL AERONAUTICS AND
SPACE ADMINISTRATION

POSTMASTER: If Undeliverable (Section 158 Postal Manual) Do Not Return

"The aeronautical and space activities of the United States shall be conducted so as to contribute . . . to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."

— NATIONAL AERONAUTICS AND SPACE ACT OF 1958

NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

TECHNICAL MEMORANDUMS:

Information receiving limited distribution because of preliminary data, security classification, or other reasons.

CONTRACTOR REPORTS: Scientific and technical information generated under a NASA contract or grant and considered an important contribution to existing knowledge.

TECHNICAL TRANSLATIONS: Information published in a foreign language considered to merit NASA distribution in English.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities. Publications include conference proceedings, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

TECHNOLOGY UTILIZATION

PUBLICATIONS: Information on technology used by NASA that may be of particular interest in commercial and other non-aerospace applications. Publications include Tech Briefs, Technology Utilization Reports and Notes, and Technology Surveys.

Details on the availability of these publications may be obtained from:
